

# **EXHIBIT U**

**Northwell Health  
Occupational Medicine, Epidemiology and Prevention**

September 22, 2017

Donald Blydenburgh, Esq.  
Levy Konigsberg, LLP  
800 Third Avenue, 11th Floor  
New York, New York 10022

Re: Helene Kohr

Dear Mr. Blydenburgh:

I am writing to report the results of my evaluation of the materials listed below pertaining to Ms. Helene Kohr. I have reviewed these materials in the context of my pre-existing knowledge, training, and experience in the field of occupational medicine. These materials are of the type I and other specialists in occupational medicine normally rely upon and are sufficient to form a reliable basis for my opinions contained within this report. All of the opinions stated in this report are given within a reasonable degree of medical certainty.

This report and the opinions stated in the report are based on the listed materials and my 25 years of training, education, and experience in the area of asbestos-related occupational medicine. Over the past 25 plus years, I have had the opportunity to evaluate and treat hundreds of patients with asbestos exposure, many of whom have asbestos related diseases.

**Qualifications:**

I am a physician licensed in the State of New York, specializing in the field of occupational and environmental disease. I have been a practicing physician since I graduated from medical school in 1988.

I attended the University of Chicago and received a Bachelor of Arts degree with Honors, with a major of History, Philosophy and Social Studies of Science and Medicine. I then continued at the University of Chicago – Pritzker School of Medicine, where I obtained my medical degree in 1988. I was elected to the Alpha Omega Alpha Honor

Society, and was also awarded an American Medical Women's Association Award. Following medical school graduation, I was an intern and resident in Internal Medicine at Yale University – Yale New Haven Hospital from 1988 – 1991. Upon completion of my Internal Medicine Residency program, I completed a second residency at the Mount Sinai School of Medicine in Occupational Medicine, from 1991 – 1993. During my Occupational Medicine Residency Program, I obtained my Master of Science Degree in Community Medicine (equivalent degree to a Masters of Public Health) in 1993. I began to evaluate dozens of patients with asbestos exposure during my residency program at Mount Sinai. I am board certified in Occupational Medicine and in Internal Medicine. I have become recertified in Internal Medicine two times.

Following completion of my residency training in Occupational Medicine, I was awarded a Fellowship in Occupational Medicine from the Foundation for Occupational Health and Research. I continued at Mount Sinai, where I joined the faculty, and continued to evaluate patients with asbestos exposure. I became Vice Chair of the Department of Preventive Medicine in 2001. I was Director of the New York/New Jersey Education and Research Center from 2006 – 2010, and had been Director of the Residency Program in Occupational Medicine from 1998-2006. I was also the Director of the Mount Sinai World Trade Center Medical Monitoring and Treatment Program from 2006 – 2010, although my involvement with the World Trade Center medical programs started in 2001, when I began to evaluate patients with exposure to the World Trade Center disaster, and was initially Medical Core Director of the World Trade Center Worker and Volunteer Medical Screening Program (2002-2004), and Co-Director of the World Trade Center Medical Monitoring and Treatment Program (2004-2006). I have published over fifty articles in the peer-reviewed literature.

In 2010, I left the Mount Sinai School of Medicine to become the Founding Chair of the Department of Population Health at Northwell Health and Hofstra Northwell School of Medicine (formerly known as North Shore University Health System). The Department changed its name in 2014 to Occupational Medicine, Epidemiology and Prevention.

I have evaluated hundreds of patients with asbestos exposure in my career in occupational medicine, spanning over 25 years. I currently direct the Occupational and Environmental Medicine Center of Long Island, providing occupational health services to patients in the metropolitan New York area. Over the past year alone, I have supervised the examination of or directly examined nearly 600 patients with asbestos exposure, as we have greatly expanded our clinical services. Over the course of the past 25 years, I have evaluated dozens of patients with malignant mesothelioma and lung cancer due to asbestos exposure. I have kept abreast of the scientific and medical literature regarding the diagnosis and causation of mesothelioma. I have personally evaluated cases of mesothelioma where the exposure was brief, and have also seen cases of mesothelioma in individuals whose only exposure to asbestos was from family members who worked with asbestos and brought their asbestos contaminated clothes home.

### **Materials Reviewed:**

I have had the opportunity to review the medical records and deposition transcripts related to Ms. Kohr. I was provided with the following information:

1. Rush University Medical Center – Pathology Reports
2. Advocate Lutheran General Hospital – Medical Records
3. Evanston Kellogg Cancer Center – Medical Records
4. Medical Care Group – Medical Records
5. Northshore Hospice – Medical Records
6. North Shore University Health System, Evanston Hospital – Path Records
7. Rush University Medical Center – Medical Records
8. Rush University Medical Center – Pathology Reports
9. University Health System, Evanston Hospital – Medical Records
10. Plaintiffs’ Certified Responses to Defendant’s Master Interrogatories
11. Video Deposition of Harvey Kohr, dated February 27, 2017
12. Video Deposition of Marilyn Mason, dated February 3, 2017
13. Deposition of Elisa Kohr, dated March 30, 2017
14. Deposition of Sheryl Salzman, dated March 31, 2017
15. Death Certificate
16. Expert Report of Dr. Steven Compton, dated September 13, 2017

### **Ms. Kohr’s Medical and Exposure History:**

Clinical History: Ms. Kohr was an 81 year old woman who was in her usual state of health until she developed worsening dyspnea on exertion, fatigue, and significant weight loss. She had lost around 12 pounds by August 2015 and an additional 9 pounds (total 19 pounds compared to 2014) by October 12, 2015. Ms. Kohr went to see her primary care physician, Dr. Laura LaFave, on October 12, 2015. She noted shortness of breath over the prior few weeks. Dr. LaFave noted decreased breath sounds in the right base. Dr. LaFave ordered a chest x-ray. The chest x-ray showed a right pleural effusion and hydropneumothorax.

A CT scan of the chest on October 16, 2015 showed a 5.4 x 5.7 centimeter lung mass with pleural nodularity and a moderate to large right pleural effusion with right hydropneumothorax. Multiple small mediastinal lymph nodes were present. An enlarged anterior mediastinal lymph node was seen. Ms. Kohr had a fine needle biopsy and thoracentesis with one liter of fluid removed on October 22, 2015. The biopsy showed a malignant epithelioid neoplasm. The cytological review of the fluid showed malignant cells present, suggestive of mesothelioma.

Dr. Michael Liptay, a thoracic surgeon, saw Ms. Kohr on October 29, 2015. She had improved breathing after the thoracentesis but it had recently worsened. She noted overall fatigue and had noted a 25-pound weight loss over the prior six months. Dr.

Liptay noted that the pathology was uncertain from the fine needle aspiration and planned a right video thoracoscopy (VATS), drainage of the effusion, biopsy, and talc pleurodesis.

Ms. Kohr was admitted to Rush University Medical Center on November 2, 2015. Dr. Liptay performed a flexible bronchoscopy that showed no endobronchial lesions. He removed 500 cubic centimeters of fluid from the right chest. He noted gross nodular tumor involvement of the visceral and parietal pleura. He took several biopsies and then insufflate talc into the chest. Ms. Kohr had no post-operative complications and she was discharged on November 5, 2015. Her oxygen saturation on room air was 88% and decreased to 82% with ambulation. She was placed on supplemental oxygen at the time of discharge. The pathology showed malignant mesothelioma, epithelial cell type. The cytological review of the pleural fluid showed rare atypical cells consistent with involvement with mesothelioma.

Ms. Kohr returned for a follow-up visit to Dr. Liptay on November 12, 2015. A chest x-ray done that day showed no significant pneumothorax, but there was an accumulation of pleural fluid, equaling a small to moderate pleural effusion. There were anterior pleural masses seen up to 6 x 4.5 centimeters and a 1.5 centimeter soft tissue pulmonary nodule. Scoliosis was also seen. Dr. Liptay noted she had fatigue and mild dyspnea with activity, and referred her to oncology for further care with single agent Pemetrexed.

Dr. Nicholas Campbell, a medical oncologist, saw Ms. Kohr on November 23, 2015, for treatment of her stage III, T3N1M0 mesothelioma. She had pain at the surgical site that was worse with deep breaths or movement. The pain radiated around her chest. She had insomnia, lack of energy, and decreased appetite with worsening fatigue. Dr. Campbell planned chemotherapy with platinum/Pemetrexed. He did not recommend surgery or radiation unless it was targeted at a specific location such as a portal site. Ms. Kohr returned to Dr. Campbell on November 27, 2015 to start chemotherapy. However, her performance status had declined. She was spending most of the day sleeping. Ms. Kohr elected not to receive chemotherapy and was referred to hospice care. She was enrolled in Northshore Hospice on November 29, 2015.

No additional medical records were available for my review. Ms. Kohr died on January 18, 2016. She was 81 years old.

Past Medical History: Ms. Kohr had left breast cancer and uterine (endometrial) cancer. She was treated with radiation for the breast cancer in 1999. She had surgery for the endometrial cancer in 2011. She had lumbar radiculopathy and a laminectomy in 2000, chronic hepatitis C, diverticulosis, hypercholesterolemia, and hypertension.

Cigarette Smoking History: Ms. Kohr smoked Chesterfield cigarettes starting as a pre-teen and teenager. She started smoking Kent cigarettes in 1952 and continued to smoke Kent until the 1970s. She smoked both regular and King Size Kent cigarettes. She smoked one to two packs of cigarettes per day while she was smoking Kents. In the

1970s until the mid-1980s, Ms. Kohr smoked approximately two packs of cigarettes a day. She quit in the mid-1980s. She had an approximate 50-60 pack-year smoking history. Ms. Kohr's husband recalled that she was smoking a cigarette the first time he met her in 1955, and she was smoking Kent cigarettes. Ms. Kohr's sister, Marilyn Mason, recalled Ms. Kohr smoking Kent cigarettes starting in 1952; Ms. Mason also smoked Kent cigarettes.

Occupational and Environmental History: Ms. Kohr used talcum powders from the 1950s until the 1990s. She used Cashmere Bouquet, Coty Airspun and Helena Rubinstein. Mr. Kohr recalled that Ms. Kohr used Cashmere Bouquet on her daughters when she changed their diapers. She also applied the Cashmere Bouquet to her body. Mr. Kohr recalled that she applied the powder after her shower daily in her bathroom, and there would be residual powder present. He also recalled applying powder to his daughters after their baths when they were older. Mr. Kohr believed his wife used Cashmere Bouquet until the 1980s. Ms. Mason recalled that her sister used the Cashmere Bouquet powder when they were living together at home prior to their marriages. Ms. Mason also recalled that she used both Johnson and Johnson baby powder and Cashmere Bouquet on her children. Ms. Kohr's daughters recalled her using Coty Airspun face powder and applying it to her face. Ms. Kohr used a powder puff to apply the powder. Elisa Kohr noted that the bathroom was always dusty as a result of her mother's use of the face powder. Elisa Kohr recalled that her mother used Cashmere Bouquet powder. Ms. Kohr switched to a compact face powder in the 1980s. Her daughter Sheryl Salzman also remembered that her mother used the Coty Airspun Face powder on a regular basis. Ms. Salzman recalled that her mother used the Coty face powder from 1963 or 1964 until the late 1970s. Her mother applied the powder every morning and in the evenings if her mother were going out. She would put powder on the velour puff, tap the powder and then apply it to her face. Ms. Salzman recalled that her mother used Cashmere Bouquet after taking a shower. She also noted that her parents would use Cashmere Bouquet when changing the diapers of her younger sisters, and that they shook the powder onto the babies. Ms. Salzman noted that her mother would shake the powder on her legs and then use a white powder puff to apply it to her chest and under her arms. Ms. Kohr also applied Cashmere Bouquet inside her girdle which her daughter recalled made it easier to get the girdle on.

Ms. Kohr worked in office jobs and at a tape supplier/re-seller. She has no known occupational exposure to asbestos.

Conclusion: Ms. Kohr had malignant mesothelioma of the pleura as a result of her exposure to asbestos from Kent cigarettes and cosmetic talc. She underwent diagnostic surgery, but elected not to receive palliative chemotherapy.

Based on the information available, it is my opinion, to a reasonable degree of medical certainty that Ms. Kohr's exposure to asbestos-containing Kent cigarettes, talcum powder, and asbestos-containing facial powder led to the development of her mesothelioma. She began smoking Kent cigarettes when the Micronite filter was introduced in 1952 and continued with this brand for years after the Micronite filter was

discontinued, but smoked during the entire time period that crocidolite asbestos was included in the filter of the cigarettes (1952-1956). She used Cashmere Bouquet talcum powder starting in the 1950s and Coty Airspun face powder in the 1950s and continued to use it until the 1980s.

The methodology and basis for my opinions follows standard methods of the medical and scientific community. Asbestos is the most well known cause of mesothelioma, and the causation of mesothelioma has been established by the quantitative history of exposure to asbestos. Thousands of individuals, from myriad professions and exposure situations have developed mesothelioma as a result of either direct or indirect exposure to asbestos. The reliance on the history of exposure to asbestos was used by seminal studies by Newhouse, Wagner and Selikoff in the 1960s, who attributed mesothelioma to asbestos exposure based solely on the history of exposure. The increased risks for mesothelioma exist for individuals who both worked directly with asbestos products and for those who worked adjacent to or in the vicinity of others who were using asbestos products, which is known as “bystander” exposure.

*Asbestos and Malignant Mesothelioma General Opinions:* Occupational Medicine is the field of medicine that deals with exposures to substances, toxins, conditions and agents in the workplace that are associated with increased risks of diseases. It exists as a subspecialty of Preventive Medicine that deals with identifying ways to prevent people from becoming ill. This includes identifying the sources, agents or catalysts that increase the likelihood of someone developing a disease, illness, or detrimental condition, and educating people on how to eliminate, avoid, and/or mitigate those risks. To put it simply, Occupational Medicine and Preventive Medicine involves searching for and identifying causes of diseases. This knowledge is important for those who are already ill: elimination of the catalysts can eliminate or mitigate the illness. It is also important from a public health point of view: to a large extent, the higher purpose of Occupational Medicine and Preventive Medicine is to educate and warn the public on how to eliminate, avoid, or mitigate the risks of diseases at the workplace, and to provide guidance to governments and businesses on appropriate regulations and standards concerning workplace health and safety.

One of the essential tasks of a physician of Occupational Medicine, when dealing with an individual patient, is the taking of a proper occupational history. Standard medical histories usually involve the patient explaining their reason for seeking medical attention; a listing of current symptoms, conditions, allergies, medications and other relevant medical problems; and providing some family and social history. Occasionally, a standard medical history may-but doesn't always-include identifying the patient's occupation.

A full occupational history, on the other hand, will go into details of a patient's entire work history, including details concerning their tasks and duties and their working conditions and environment. The history will also routinely make inquiries into the patient's home or hobbies. It would also reveal what kinds of substances or agents the patient was exposed to in his or her working environment that might have occurred

decades earlier. It remains the standard tool for determining exposure and has not been supplanted by quantitative measurements, which are rarely obtained, and would not, unless continuously performed on an individual (which is not feasible), fully address all exposures an individual might have had. At times, it is not possible to directly obtain an occupational history from an individual, and information concerning work and environmental experiences contained in deposition transcripts by plaintiffs, co-workers and family members can provide detailed information of that type that can be elicited from an occupational physician-obtained history.

The hallmark of occupational medicine is to connect an exposure to a hazardous substance to a disease, and identify whether there is a causal relationship. This is a critical differentiation in the field of occupational medicine; not only do we treat patients for disease, but we emphasize what hazardous substance might be causing the disease. In occupational medicine training, there are core areas of training, including epidemiology, biostatistics, toxicology, and industrial hygiene.

**Asbestos and Disease:** Asbestos is a naturally occurring mineral that has been used commercially for a variety of purposes for over 100 years. Asbestos is mined in the form of microscopic fibers released from the surrounding earth. Asbestos was extremely useful from an industrial perspective: it is highly resistant to heat and therefore serves as an excellent insulator and friction surface. It is also very durable, and as a fiber it can be molded into shapes and products that serve a variety of functions. However, asbestos is also highly toxic and carcinogenic when the fibers are inhaled or ingested.

While there are many “fiber types” of asbestos, as well as different sizes of the fibers, there exists consensus among scientists that exposure to *any* asbestos fiber type or size increases the likelihood of lung cancer, mesothelioma, as well as nonmalignant lung and pleural disorders. Asbestos fibers are generally divided into two categories: amphiboles and serpentine (or chrysotile). There are several varieties of amphiboles, including both commercial and non-commercial types. The three major asbestos types used in industry have been chrysotile, amosite and crocidolite. Of these three fiber types, over 95% of all asbestos used in the United States has been chrysotile. Much of the chrysotile asbestos that was used in the US was mined in Canada, where there was contamination with small amounts of tremolite, another type of amphibole asbestos. The mainstream scientific community has also long recognized, and continues to recognize today, that there is no “safe” level of exposure to asbestos regardless of fiber type or size. This position is shared by numerous United States government agencies, including the Occupational Safety and Health Administration (“OSHA”, which has regulatory authority over workplaces), the Environmental Protection Agency (“EPA” which has regulatory authority over non-occupational settings), the National Institute for Occupational Safety and Health (“NIOSH”, which is responsible for conducting research and making recommendations for the prevention of work-related injuries and illnesses), the World Trade Organization (“WTO”), and the national academies of science of every major industrialized nation. The World Health Organization recently reviewed the existing literature and concluded (in 2014) that all fiber types are capable of causing asbestos

related disease, including mesothelioma, and reiterated the statement that there is no safe level for exposure to asbestos.

Due to the ubiquitous use of asbestos and its presence in naturally occurring formations, there is asbestos in the ambient air in the United States, albeit at minute levels. The ambient air concentration or “background level” has been reported to range from 0.0005 f/cc in urban areas, to 0.00005 f/cc in rural regions. These levels are thousands of times less than the current OSHA permissible exposure level of 0.1 f/cc. While it is theoretically possible to develop mesothelioma from ambient air concentrations, it has not been proven to occur at levels at or below ambient air concentrations. Given that there is no truly “unexposed” population, it would be impossible to reasonably perform such a study to determine if this were the case.

### **State of the Art:**

In 1898 Montague Murray described interstitial fibrosis in an individual exposed to asbestos. Pancoast described radiographic changes of interstitial fibrosis in asbestos workers in 1917. Cooke described two cases of asbestosis in the 1920s, and actually used the term “asbestosis” to describe the interstitial fibrosis among asbestos workers, and also noted pleural plaques (fibrosis) in these workers.

In 1930 Merewether and Price, in their *Report on the Effects of Asbestos Dust on the Lungs and Dust Suppression in the Asbestos Industry*, noted that inhaling dust containing asbestos fibers could lead to disabling and fatal lung disease. They studied asbestos workers in the textile mills in Great Britain, and noted that asbestosis could occur in large numbers of exposed individuals. Moreover, they found that the textile workers with the highest exposures had more asbestosis than workers in areas where asbestos exposure was lower. Merewether and Price noted that asbestos was a potential hazard to health in any industry where dry asbestos products were abraded or otherwise manipulated to generate dust, such as thermal insulating. They recommended warning, education and training of all those individuals who were exposed to asbestos.

Lynch and Smith noted a case of lung cancer in an asbestos worker from South Carolina in 1935. Textbooks in the 1930s, such as A.J. Lanza’s textbook on dust disease, included asbestosis as a disease of concern. In 1943, the first case of mesothelioma was associated with asbestos exposure and was published by Wedler in Germany. Also in 1943, Hueper from the United States Public Health Service stated that he believed asbestos caused lung cancer. He published an editorial stating this association in the Journal of the American Medical Association in 1949.

In 1955, Doll published a seminal article that described the increased risk of lung cancer among asbestos exposed workers. By the time of Doll’s epidemiology study, there had been over 60 cases of asbestos-related lung cancer published in the literature. In 1960, Wagner et.al. published a study of 33 cases of malignant mesothelioma among individuals who were exposed to asbestos in and around the crocidolite mines in South Africa. Not only were miners developing disease, but family members, individuals on the wagon routes in which the asbestos was carried and people who had played with mine

tailings as children developed mesothelioma. In the early 1960s numerous studies in several countries, under different exposure scenarios, were published that showed mesothelioma in association with asbestos exposure. In fact, by the end of 1964, over 700 scientific articles had been published that showed the adverse health effects of asbestos.

*The Development of Diseases:* When asbestos is inhaled, some proportion of the fibers can be deposited upon any component of the respiratory tract, including the nose, pharynx, conducting airways and the alveolar or gas exchanging regions of the lung. Fibers that land initially on the airways and above are cleared rapidly from the lung. The primary defense mechanism that mediated this clearance is known as the mucociliary escalator. The escalator is comprised of ciliated and mucus producing epithelial cells that propel inhaled fibers up to the mouth where they can be swallowed or expectorated. These epithelial lining cells are the “target cells” for cancers. Fibers that evade the mucociliary escalator can penetrate into the lower airways and lung tissue, where they can be transported through the body. Amphibole fibers tend to clear from the lung less rapidly than chrysotile fibers. Asbestos is cleared through the pulmonary lymphatics to lymph nodes and to the pleura, the target organ for pleural mesothelioma. Of the different fiber types, Suzuki, Sebastien and LeBouffant have all shown that chrysotile fibers preferentially translocate to the pleural space.

*Asbestosis:* The fibers that are inhaled and deposited past the escalator can cause asbestosis. These fibers deposit initially on the Type 1 and Type 2 alveolar epithelial cells. On the epithelial surfaces, some asbestos fibers activate the 5<sup>th</sup> complement which attracts inflammatory cells, including foreign particles, like asbestos, from the lung. About 20% of the fibers deposited on the alveolar surfaces are enveloped by the Type 1 cells and are translocated to the underlying connective tissue (interstitial) compartment. There, the fibers can interact with interstitial fibroblasts, myofibroblasts and macrophages. Fibroblasts and myofibroblasts are the target cells for asbestos because these are the cells that synthesize and release the scar tissue matrix. (See Y. Suzuki & N. Kohyama, *Translocation of Inhaled Asbestos Fibers from the Lung to Other Tissues.*, 19 Am J. Indus. Med. 701 (1990); Y. Suzuki & N. Kohyama, *Translocation of Inhaled Asbestos Fibers from the Lung to Other Tissues.*, 19 Am J. Indus. Med. 701 (1991)). They produce scar tissue when the epithelial cells are injured and when the macrophages are activated. Alveolar cells and macrophages release a number of protein growth factors that stimulate the fibroblasts to multiply and produce scar tissue and the fibroblasts and myofibroblasts also synthesize a similar array of factors that induce their own cell growth and matrix production that we recognize as asbestosis. Like *all* of the asbestos-related diseases, asbestosis is dose dependent. An individual typically needs long-term occupational exposure to develop clinical asbestosis.

The scarring process described above begins as soon as inhaled fibers are deposited on the alveolar surfaces, and microscopic asbestosis is ongoing in the lungs of afflicted individuals for many years before any clinical signs or symptoms are presented. The initial physiological symptom of asbestosis is shortness of breath. This is caused by the scar tissue which replaces normal elastic connective tissue, this producing a stiff lung that restricts the individual from taking a deep breath. Shortness of breath also results

when scar tissue thickens the alveolar-capillary membrane, the barrier across which oxygen and carbon dioxide gases are exchanged.

Pleural Plaques and Fibrosis: This is scar tissue formation in an identical manner to that described above, under asbestosis. The difference is that there is little direct deposition of asbestos fibers in the pleura. While some fibers can be inhaled through the alveolar ducts and reach the pleura directly, most fibers that land on alveolar surfaces and reach the interstitial compartment have direct access to the pleura do so by way of pulmonary lymphatic flow. The inhaled fibers that land on alveolar surfaces and reach the interstitial compartment have direct access to lymphatic fluids which flow through these regions on the way to the pleura. The lymphatic flow carries fibers to the pleura where they interact with the sub-mesothelial fibroblasts that produce a scar tissue matrix, as described above. If the scarring is in a circumscribed pattern, the scarring is called “plaque”. Investigators have shown that this injury can result in a restrictive lung disease in some individuals.

Lung Cancer: These tumors caused by asbestos typically arise in cigarette smokers, although some epidemiologic studies on asbestos-exposed non-smokers show an increased risk of developing the disease. When an individual is exposed to the cancer-causing agents (carcinogens) of both cigarettes and asbestos, the risk of getting lung cancer is increased well beyond the risk presented by exposure to either agent alone or by simply adding the risks of the two carcinogens. Epidemiologists multiply the risks of the two carcinogens since there is a clear synergy in the way asbestos and cigarette smoke combine to cause lung cancer.

Cancer is the loss of control of cell growth. Every cell in the bodies of humans and animals is under strict genetic control of the rate at which a given cell replaces itself by dividing. Cancer is caused when the specific genes that control cell division and other aspects of the cell cycle develop errors or mutations. Carcinogens induce such errors, and complete carcinogens can produce the errors with no other agent required. Cigarette smoke has a number of complete carcinogens, and all of the asbestos varieties have been shown to act as complete carcinogens. Thus, as the airway epithelial cells of the mucociliary escalator are assaulted daily by cigarette smoke and asbestos fibers, a number of cells are injured, and many exhibit genetic errors through the lifespan of the individual. In those who are susceptible to developing a cancer, one of those injured cells accumulates a sufficient number of genetic errors in genes that control cell growth to finally, after decades of exposure, lose the normal growth pattern and grow into a malignant tumor. (See Frost G, Darton A, Harding AH. *The effect of smoking on the risk of lung cancer mortality for asbestos workers in Great Britain (1971-2005)* Ann Occup Hyg 55:239-24 (2011)).

Mesothelioma: This cancer occurs when a mesothelial cell of the pleural or peritoneal surfaces develops a sufficient number of genetic errors in a set of genes that control cell growth, as described above. Cigarette smoking has no influence on the development of mesothelioma. (See N.S. Offermans, et. al., *Occupational Asbestos Exposure and Risk of Pleural Mesothelioma, Lung Cancer, and Laryngeal Cancer in the Prospective Netherland Cohort Study*, 56 J. Occupational Envt'l Med. 1 (2014); Robinson BM.

*Malignant pleural mesothelioma: an epidemiological perspective*, 1 Annals Cardiothoracic Surgery 491 (2012)).

Asbestos exposure is the only known occupational and/or environmental cause of mesothelioma in North America, and all of the asbestos varieties induce the genetic errors described above and cause this cancer. The fibers that cause mesothelioma reach the pleural surfaces through the lymphatic pathways, as explained earlier, and they interact with the target cells of the mesothelial surfaces. When a sufficient number of genetic errors have accumulated in a single mesothelial cell, this cell can undergo neoplastic transformation and grow into a deadly tumor. It typically takes many decades for a sufficient number of mutations to occur in a single mesothelial cell because of the numerous effective defense mechanisms that destroy genetically defective cells, thus explaining the long latencies known for this cancer.

All of the asbestos varieties have been shown to cause genetic errors and fibers less than five microns can bind DNA and this contributes to the development of genetic damage. Short fibers have been found to accumulate in the pleural regions of the lung as well as in mesenteric lymph nodes of the peritoneal cavity. Longer fibers may be comparatively more dangerous than short fibers (on a fiber per fiber basis), but all size ranges are capable of causing and contributing to the development of mesothelioma or any of the asbestos-related diseases. Exposure to asbestos fibers of all types and lengths are toxic, and short fibers more readily reach the mesothelial target cells of the pleura. (See Y. Suzuki & S. R. Yeun, *Asbestos Fibers Contributing to the Induction of Human malignant mesothelioma.*, 982 Annals N.Y. Acad. Sci. (2002); Y. Suzuki, et al. *Short thin asbestos fibers contribute to the development of human malignant mesothelioma: pathological evidence.*, 208 Int'l. J. Hygiene Envtl. Health 201 (2005)). Fibers of all lengths can bind to DNA and cause genetic errors that are required in the causation of cancer such as mesothelioma. Fiber burden studies of mesothelioma patients show a preponderance of chrysotile asbestos within the tumor tissue. Since the target location of mesothelioma is the pleura, the lung burden of asbestos does not reflect the fact that asbestos has moved from the lung to the pleura, where it can cause the mesothelioma to develop. (See Ronald F. Dodson, *Analysis and Relevance of Asbestos Burden in Tissue, in Asbestos: Risk Assessment, Epidemiology and Health Effects.* Risk Assessment, Epidemiology and Health Effects 78 (2d, ed. 2011); M. Silverstein, et al., *Developments in Asbestos Cancer Risk Assessment.* Am J. of Indus. Med. (2009).

Moreover, there is ample evidence to support the conclusion that exposure to the asbestos fibers typically used in brake linings-chrysotile fibers-can and does cause mesothelioma. This conclusion is supported by, among others, the American Conference of Governmental Industrial Hygienists, the American Thoracic Society, the Environmental Protection Agency, the International Agency for Research on Cancer, the National Toxicology Program, OSHA, the Consumer Products Safety Commission, the World Health Organization, and the World Trade Organization. The scientific consensus that all fiber types and sizes can cause mesothelioma is also reflected in the Consensus Report of the 1997 Helsinki Conference (discussed below) and publications from the

American Cancer Society and the National Cancer Institute of the National Institutes of Health.

In essence, there exists a consensus among the overwhelming majority of medical and scientific professionals and organizations that asbestos fibers of any type or size can cause mesothelioma, including chrysotile fibers. (See Dodson, Ronald F. et al., *Asbestos Fiber Length as Related to Potential Pathogenicity: A Critical Review*, 44 Am J. Indus. Med. 291 (2003); D. Egilman, et al., *Exposing the "Myth" of ABC, "Anything But Chrysotile: A Critique of the Canadian Asbestos Mining Industry and McGill University Chrysotile Studies*. 44 Am J. Indus. Med. 540 (2003); David S. Egilman & Marion Billings: *Abuse of Epidemiology: Automobile Manufacturers Manufacture a Defense to Asbestos Liability*, 11 Int. J. Occupational Envtl Health 360 (2005). 11:360-371; Egilman D. *Fiber Types, Asbestos Potency, and Environmental Causation*. 15 Int. J. Occupational Envtl. Health (2009); Finkelstein, M. *Asbestos Fiber Concentrations in the Lungs of Brake Workers: Another Look*, 52 Annals Occupational Hygiene 455 (2008); M.M. Finkelstein & C. Asbestos fibers are very small; so small, in fact, that millions of fibers could fill the air in a room without anyone being able to perceive it with the naked eye. The fibers are odorless, cannot be seen with the naked eye, and are aerodynamic. Consequently, someone can inhale asbestos fibers without even being aware of it. The fibers are also small enough to pass through the normal respiratory defense mechanisms that the human body uses to keep out toxins and debris.

The Scientific community has even concluded that small amount of asbestos exposure can cause cancer. The Rodelsperger study indicates that exposure to asbestos below the Occupational Safety and Health Administration (OSHA) Permissible Exposure Level (PEL) of 0.1 fibers per cubic centimeter can cause disease. However, visible asbestos-laden dust that is released into the air from the manipulation of gaskets or packing, or that is reintroduced into the respirable zone from the process of sweeping the

floor, is between 2.0 and 10.0 fibers per cubic centimeter. These levels far exceed the OSHA PEL. Some of these levels even exceed the OSHA PEL issued in 1972.

Government agencies and international organizations universally recognize asbestos as a carcinogen in low levels. These agencies include the International Agency for Research on Cancer, Environmental Protection Agency, OSHA, National Institute for Occupational Safety and Health, and World Health Organization. The inhalation of asbestos fibers also does not trigger any immediate physiological reactions: the victim doesn't experience any immediate irritation, asthmatic problems, or allergic reactions. Moreover, the latency, or development period, for mesothelioma is very long: the minimum latency period is usually considered to be around 10 years with a maximal latency period well over 60 years after the last exposure. Consequently, it could be decades before someone is aware that he or she was exposed to asbestos, or it might have occurred so remotely that they do not realize they had asbestos exposure. Moreover, they may not realize that a product they used contained asbestos and thus are unaware they had exposure.

*The Helsinki Criteria for Attribution:* In January 1997, a conference called “Asbestos, Asbestosis and Cancer” was held in Helsinki, Finland. The conference was convened to establish criteria for diagnosis and attribution of disorders of the lungs and pleura, including mesothelioma. This was a multidisciplinary group of internationally recognized experts, consisting of pathologists, radiologists, occupational and pulmonary physicians, epidemiologists, toxicologists, industrial hygienists, and clinical and laboratory scientists specializing in tissue fiber analysis. Collectively, the members had published over 1,000 articles on asbestos and associated disorders. The conclusions of the conference were developed into a peer-reviewed Consensus Report that established the “Helsinki Criterion”. Among the conclusions of the Helsinki Criterion are:

- a. That, in general, reliable work histories provide the most practical and useful measures of occupational asbestos exposure; and
- b. That even in the absence of other independent evidence of disease (e.g. lung fiber counts exceeding the background range for the lab in question; the presence of radiographic or pathological evidence of asbestos-related tissue injury; histopathologic evidence of abnormal asbestos content), a history of significant occupational, domestic or environmental exposure to asbestos will suffice for attribution of the disease with asbestos exposure.

Moreover, with reference to determining an occupational etiology of mesothelioma, the Helsinki Criterion Consensus Report concluded that:

- a. The great majority of mesotheliomas are due to asbestos exposure;
- b. Mesothelioma can occur in cases with low asbestos exposures. However, very low background environmental exposures carry only an extremely low risk;

- c. About 80% of mesothelioma patients have had some sort of occupational exposure to asbestos (necessitating a carefully obtained and detailed occupational history for proper diagnosis);
- d. An occupational history of brief or low-level exposure should be considered sufficient for mesothelioma to be designated as occupationally related;
- e. A minimum of 10 years from the first exposure is required to attribute mesothelioma to asbestos exposure (though in most cases, the latency interval is longer);
- f. Smoking has no influence on the risk of mesothelioma.

The conclusions of the Helsinki Criterion have since been adopted by, and form the general consensus of, the medical community's positions vis-à-vis mesothelioma and asbestos. (See *Consensus Report, Asbestos, asbestosis and cancer: the Helsinki criteria for diagnosis and attribution*, 23 Scandinavian J. Work Environ Health 311 (1997)). And, given the fact that about 80% of patients with mesothelioma have had some sort of occupational exposure to asbestos,<sup>1</sup> asbestos exposure in the workplace is a prime focus of Occupational Medicine when dealing with mesothelioma patients.

*Mesothelioma is a dose responsive disease:* It is my opinion that Mesothelioma and asbestos related lung cancer are dose responsive diseases in which more substantial exposures directly increases the risk for the development of these cancers. This linear dose-response relationship presented in *Asbestiform Fibers: Non-occupational Health Risks*, published by the National Research Council National Academy of Sciences in 1984, discussed herein, is neither new nor novel and generally accepted in the medical and scientific communities. As per the aforementioned Helsinki criteria, the first question usually asked of a patient diagnosed with mesothelioma, concerns how, when, and where the patient was exposed to asbestos. (See *Consensus Report, Asbestos asbestosis and cancer: The Helsinki criteria for diagnosis and attribution*. 23 Scandinavian J. Work Environ Health 311 (1997)). Because of the proven association between asbestos fibers and mesothelioma, proof of significant exposure to asbestos dust is considered to be proof of specific causation. (See P. Boffetta, et al., *Health Effects of Asbestos Exposure in Humans: A Quantitative Assessment*. 89 (6) Medicina Del Lavoro, 471 (1998). This causal relationship between exposure to asbestos dust and the development of mesothelioma is so firmly established in the scientific literature that it is accepted as a scientific "fact".

Malignant mesothelioma is, in general, a dose response disease where each and every significant exposure to asbestos-containing dust has been shown to contribute to cause diffuse malignant mesothelioma including pleural mesothelioma (See also Newman, et al., *Malignant Mesothelioma Register 1987-1999*. 74 Int'l Arch Env. Health 383 (2001), (concluding that "higher cumulative asbestos-fiber dose leads to the earlier development of mesothelioma)). As each exposure to asbestos contributes to the total

---

<sup>1</sup> The remaining 20% of mesothelioma patient likely had asbestos exposures that were para-occupational or are simply unidentified.

amount of asbestos that is inhaled, and, in doing so, reduces the necessary period for asbestos disease to develop. Therefore, each non-trivial exposure to asbestos should be considered a substantial contributing factor in the development of the malignant mesothelioma or lung cancer.

*Exposure to Asbestos contaminated talc and disease*

Asbestos fibers have been reported in cosmetic talcum powder for decades, in company documents, the media, FDA communications, and the published medical and scientific literature. Cosmetic talc has been analyzed by researchers in various countries, and has routinely been shown to be contaminated with asbestos. Exposure to asbestos contaminated talc has been shown to cause asbestos related diseases, including mesothelioma. In 1976 Rohl and Langer tested 20 consumer products that had been labeled as talc or talcum powder, including body powders. Of the 20 products that were tested, ten were found to contain tremolite and anthophyllite, principally asbestiform. Of note, the product that had the highest asbestos content in the Rohl and Langer study was the same product later tested by Gordon, et.al. This product was in fact, Cashmere Bouquet, the body talcum powder used by Ms. Kohr. A recent paper by Gordon, et.al., Asbestos in Commercial Cosmetic Talcum Powder as a Cause of Mesothelioma in Women, evaluated the mineralogical constituents of Cashmere Bouquet and its ability to release asbestos fibers into the breathing zone of the direct user and bystanders. In their paper Gordon et.al. noted that the talc that was used in Cashmere Bouquet was derived from three distinct regions, where anthophyllite and tremolite asbestos were found. Gordon et.al. measured 18 million anthophyllite asbestos fibers per gram in the talcum powder. Air measurements were done by both phase contrast microscopy (PCM) and transmission electron microscopy (TEM), and significant levels of asbestos fibers were noted (anthophyllite, tremolite and some chrysotile) in the breathing zone of the individual applying the powder as well as a bystander. Results taken from the experiment in the paper show that personal measurements from the shaker container test showed a measurement by PCM of 4.8 f/cc, with an actual asbestos fiber measurement of 1.8 f/cc. Bystander measurements showed a lower, but still significant exposure of 1.35 f/cc by PCM for the bystander, and 0.5 f/cc of actual asbestos fibers. Similar measurements were done with the puff application method. Personal measurements after using a puff were 23.6 f/cc and 16.5 f/cc for the user, with actual asbestos fiber measurements of 5 f/cc and 3.5 f/cc. A short term sample showed even higher measurements, of 60 f/cc with the use of a puff and actual asbestos fiber measurements of 13 f/cc. Bystander exposures to asbestos from the puff application were elevated, with a short term sample by PCM of 13.7 f/cc and 9.7 f/cc, and an actual asbestos fiber measurement of 4.9 f/cc and 3.5 f/cc. Gordon et.al. also noted that the TEM measurements were far more sensitive than x-ray diffraction detection, since there was a much lower detection limit with TEM.

In addition to looking at bulk and air samples, Gordon et.al analyzed the lung tissue and lymph node tissue of a woman who had been exposed to contaminated talcum powder (Cashmere Bouquet). The authors found that there were 3150 and 4150 fibers per gram wet weight, respectively, with a detection limit of 690 fibers per gram wet weight. All fibers were 5 micrometers or greater in length, and had an aspect ratio of 20:1 or greater. The fibers were identified as anthophyllite or tremolite. In addition to the fibers

counted above, there were many anthophyllite and tremolite fibers that were less than 5 micrometers in length, with a predominance of anthophyllite. In the lymph node, amphibole asbestos fibers were also noted, measuring 12,738 fibers per gram wet weight (detection limit 2123 fibers per gram wet weight). Again, the fibers noted were anthophyllite and tremolite. In addition to the asbestos found in the lungs, the authors noted fibrous and platy talc and small asbestos bodies.

The issue of asbestos and talc has been studied for decades among talc miners. Lung scarring was seen in miners from New York State in the 1950s, and there are elevated rates of mesothelioma and lung cancer in miners at the asbestos contaminated talc mines. The International Agency for Research on Cancer has noted that talc contaminated with asbestos is carcinogenic.

#### Applying an Accepted Method for Evaluating Disease Causation in an Individual

In deciding whether Ms. Kohr's mesothelioma was caused by her exposure to asbestos, I applied the methodology that was described by Welch, et.al. in her paper Asbestos Exposure Causes Mesothelioma, but Not This Asbestos Exposure: An Amicus Brief to the Michigan Supreme Court, published in 2007 in the International Journal of Occupational and Environmental Health. In this paper, she identifies four questions that should be examined in the causation of disease in an individual:

1. Was the individual exposed to a toxic agent?
2. Does the agent cause the disease present in the individual?
3. Was the individual exposed to this substance at a level where the disease has occurred in other settings?
4. Have other competing explanations for the disease been excluded?

For question #2, there is ample literature that asbestos causes mesothelioma and no dispute in the medical literature. With respect to question #1, Ms. Kohr had an exposure to asbestos from talcum powder and facial powder for many years, fulfilling this criterion. She was also exposed to asbestos from the Kent micronite filter, which contained crocidolite asbestos from 1952 – 1956 when she was smoking one to two packs of Kent cigarettes a day. Coty Airspun face powder, Cashmere Bouquet and Kent micronite filters have been shown to contain asbestos and Ms. Kohr would have had asbestos exposure based on the descriptions from her family's deposition testimony. Apart from this potential exposure, she has no other competing explanations (#4) for the development of her mesothelioma. While she did have radiation after her breast cancer, and there is a potential connection between radiation treatments and subsequent development of mesothelioma, she underwent radiation on the contralateral (left) side; there is no evidence that radiation on the contralateral side of the body is associated with the development of mesothelioma. The remaining criterion, #3 is whether there is an analogous exposure scenario in which others also developed mesothelioma. As described above, and recently published by Gordon, et.al, there are other women with exposure to contaminated talc products who then developed malignant mesothelioma.

#### **Summary and Specific Causation in Ms. Kohr's Case**

Based on the information that was provided to me, and applying both my understanding of the medical literature and the facts of this case, it is my opinion to a reasonable degree of medical certainty that the exposures to the dust from asbestos-contaminated cosmetic talc products that Ms. Kohr used for many decades, starting over 50 years ago, were above normal background levels. In fact, Rohl, in correspondence to the FDA in the 1970s noted that Coty face powder contained 11% tremolite, and tremolite asbestos was also found when Pfizer, Inc.'s Research Department analyzed the Coty Airspun Face Powder and in more recent fiber release studies of samples of these products. The bulk analysis and fiber release studies done recently by Fitzgerald and others from ore taken from the same source mines as those used in the manufacture of the Cashmere Bouquet and Coty products showed significant amounts of chrysotile, anthophyllite, and tremolite asbestos. Ms. Kohr was exposed to asbestos from Kent Micronite cigarettes, which she smoked from 1952-1956 when crocidolite asbestos was used in the filters. Studies have shown that each filter contained 10 milligrams of crocidolite asbestos and that millions of fibers of asbestos were released into the lungs during smoking. Dr. Steven Compton has personally evaluated Kent Micronite cigarettes and noted crocidolite asbestos fibers present in the Micronite filter. Longo et al tested Kent cigarettes (Cancer Research 1995) and noted crocidolite fibers in both the filters and in the cigarette smoke itself.

Her exposures to asbestos-contaminated face powder and asbestos-contaminated body powder and to Kent cigarettes were the cause of her mesothelioma. If she had not used asbestos-containing face and body powder, nor had she smoked Kent cigarettes in the 1950s, she would not have developed malignant mesothelioma.

The opinions related to Ms. Kohr's case are based on my review of the evidence of exposure in this case, the medical and scientific literature as described above regarding asbestos exposure and disease, available studies concerning fiber release, epidemiological studies of exposure to asbestos exposure and the development of disease, and my knowledge, skill, experience, and training as a physician specializing in occupational medicine with a clinical focus on evaluating individuals with asbestos exposure.

Ms. Kohr suffered and died from metastatic malignant mesothelioma of the right pleura. She had a rapid course and died around two months after she was diagnosed.

I have attached a partial reference list that indicates reliance materials for this report.

Sincerely,

Jacqueline Moline, MD, MSc, FACP, FACOEM
